Received April 1, accepted June 17, 1986

Summary. — Using low resolution IDS spectra, we try to clarify the classification of 264 objects which appeared as planetary nebulae in various listings, and were originally included in two lists of Sanduleak (1976) : (1) misclassified or doubtfully classified planetary nebulae ; (2) faint, suspected planetary nebulae. The new data show that 67 % of the objects can be considered as « true » planetary nebulae, of which 46 % present low excitation characteristics. The status of the other objects remains quite uncertain, some of them being symbiotic stars (14 %), or various emission-line objects. In 4 cases, we found no positive indication of emission-line objects in the observed areas.

Key words : planetary nebulae : classification — emission-line objects.

The set of planetary nebulae (PN), late stages in the evolution of stars of intermediate mass, is remarkably heterogeneous, showing a large variety of shapes and spectra. It is therefore possible to mistake some of them for objects showing morphological or spectroscopical similarities in connection with similar physical processes, but having quite different origin, mass, etc...

Since 1984, we have conducted a spectroscopic study of the whole system of planetary nebulae, with a double aim :

- realization of an atlas of calibrated spectra, within the framework of the new « Strasbourg — ESO catalogue of planetary nebulae » ;

- statistical study of spectroscopic properties of the PN in relation to problems on stellar evolution.

But the first aim of our work is to study as extensively as possible the true status of the just over 1500 objects which are presently called « PN ». The Catalogue of Galactic PN (CGPN) done by Perek and Kohoutek in 1967 gave the compilation of 1036 PN ; new PN are listed by Kohoutek (1977, 1983) and by Acker *et al.* (1984). Lists of misclassified objects have also appeared, showing that the material may be quite inhomogeneous.

In the present paper, we examine, through our own spectroscopic observations alone, a set of 264 PN taken from the CGPN, and listed by Sanduleak (1976) in his table I : « misclassified and doubtfully classified planetary nebulae », and table II : « faint, suspected planetary

nebulae ». A paper II (by Acker *et al.*) will present a general review of all PN given as misclassified or doubtful in the literature, including those studied here. In a paper III, we will give the lines intensities and the $I(\lambda)$ recordings of the objects classified as true or possible PN.

1. Observations.

The spectra were obtained in 1984 April, 1985 July-August, and 1986 January, with the Image Dissector Scanner (IDS) device, mounted on a conventional Boller and Chivens spectrograph on the 1.52 m telescope at the European Southern Observatory (ESO), La Silla ; details about the measurement procedure may be found in papers by Lundström and Stenholm (1984), and Stenholm (1986). The spectrum, taken at low-resolution (1 pixel = about 0.2 nm), covers a range from about 400 to about 725 nm. The aperture used is $4'' \times 4''$, well adapted for most of the objects studied here, showing small extension.

Depending on the large number of objects, the exposure time for each object must be short. We have chosen a standard exposure time of 10 min for all objects, instead of adjusting it to the brightness of the nebula. The noisiness of the resulting spectrogram then gives indirectly a measure of the faintness of the object.

Reductions and measurements were performed with the aid of the Image Handling And Processing programme (IHAP) of ESO, at Garching and at Strasbourg (using the HP 1000 computer of the « Institut de Physique du Globe »).

(*) Based on observations collected at the European Southern Observatory, La Silla, Chile.

2. Results.

Table I shows the following data, for 264 objects listed in order of their increasing galactic longitude :

2.1 NAME. — The PK number defined by Perek and Kohoutek (1967) in the CGPN ;

— the current number given by Sanduleak (1976) in his table I (objects called M1 to M179) and table II (F1 to F153) ;

— the usual name, given under the PK number.

2.2 NATURE OF THE OBJECT. — It is very difficult to define the true nature of an object. According to previous studies (Chopinet and Loretz Zuckermann, 1976 ; Sanduleak and Stephenson, 1973 ; Allen, 1978, 1984), we have adopted spectroscopic criteria related with the degree of excitation of the nebular spectrum. A PN is characterized by a high excitation, generally revealed by a high value of the ratio $I([OIII] 495.9 + 500.7)/I(H\beta)$. We have chosen the following rather empirical classification :

(1) The class PN is given for the objects showing $I([OIII])/I(H\beta) \geq 4$; for a value ≈ 7 of this ratio, the high excitation line HeII 468.6 should generally appear.

— H : means a very high excitation, shown by $I([OIII])/I(H\beta) \geq 15$, and

$$I(\text{HeII } 468.6)/I(H\beta) \geq 0.5 ,$$

or $I([OIII] 436.3)/I(H\gamma) \geq 1$.

— L : means a low excitation, corresponding to $I([OIII])/I(H\beta) = 1$ to 4, and $I(\text{HeII}) = 0$.

— VLE : means a very low excitation, corresponding to $I([OIII])/I(H\beta) \approx 0$ to 1, $I(\text{HeII}) = 0$, and $I([NII])/I(H\alpha) \approx 1$; the object should be either an HII region, or else a VLE PN.

— pos. PN? : in this class of objects, we include as possible PN the VLE nebulae with $I([OIII]) = I(\text{HeII}) = 0$, $I([NII])/I(H\alpha) \approx 1$, and exhibiting a fairly strong [SII] doublet, allowing in many cases the deduction of a high density (« hd ») for the nebulae. Considering other observations of these nebulae, it appears that they show properties typical of PN, in particular in the IR range (Pottasch, 1986, and Paper II).

(2) no PN : means ratios

$$I([OIII])/I(H\beta) = I(\text{HeII})/I(H\beta) = 0$$

or invisible, and $I([NII])/I(H\alpha) < 1$ (in most cases $H\alpha$ only visible). But in some cases, these ratios can be of higher values, the spectrum showing elsewhere characteristics of another kind of object (symbiotic star, for example). The status « no PN? » is given in these cases, and also in cases where the [OIII] and HeII lines are not detected (noted inv., 0, or 0?) and where the [NII] doublet intensity is comparable to that of $H\alpha$, the [SII] lines being very faint or invisible.

— The class « symbiotic star » is given for objects showing a red continuum with the TiO absorption bands ; high ionized lines, such as HeII, [CaVII], [FeVI], [FeVII], and the characteristic (unidentified)

683 nm (and sometimes 709) emission feature (see Allen, 1984).

— In most cases, we give no precision about the nature. The object can be an HII region, or an emission-line star, or a reflection nebulae, ...

— If no emission features are discovered around the theoretical position, it is noted that we have « no positive indication of emission lines-objects in this area », depending on bad or wrong finding charts, or misclassification problems.

(3) For some objects, we give other precisions :

— X : corresponds to steep Balmer decrements probably due to reddening ; the ratio $H\alpha/H\beta$ is high (≥ 25) and higher order Balmer lines are not detected (following the classification of Sanduleak and Stephenson, 1973).

— hd : means « high density », deduced from a high ratio of the [SII] doublet : 673.1/671.7.

— Spectral peculiarities are noted ; in particular, the estimation of the ratio $[OIII] 436.3/H\gamma$ is given, when this ratio is ≥ 1 .

2.3 DESCRIPTION OF THE SPECTRUM. — Three ratios of line intensities are estimated :

$$\begin{aligned} & [OIII] (495.9 + 500.7)/H\beta ; \\ & [NII] (654.8 + 658.3)/H\alpha , \end{aligned}$$

and $\text{HeII } (468.6)/H\beta$. The following comments are given, to allow the distinction between the different classes discussed above :

0 : means that the line I_1 is not detected in the ratio I_1/I_2 ; in the case of the blend [NII] + $H\alpha$, we note : « $H\alpha$ only », if [NII] is invisible ;

inv. : means that the two (or three) lines are undetected ;

$\gg x$: means that the ratio is higher than $2x$;

$\ll x$: means that the ratio is lower than $x/2$;

? : means that the detection is doubtful, near the limit of the resolution. In particular, the [OIII] doublet seems in some cases blended with near HeI , $FeII$ lines.

It should be noted that, in the case of surface objects, the ratios depend from the distance to the center (in the case of 331-01°1, two different estimations are given).

— Qualitative indications are done for the *continuum*, according to the mean level of the flux ϕ (calculated in $10^{-18} \text{W/m}^2/\text{nm}$) :

strong : corresponds to $\phi > 1000$;

faint : $\phi = 25$ to 300 ;

very faint : $\phi < 25$.

The mean color of the continuum is also given. The observed *absorption features* are indicated, especially the red bands of TiO.

2.4 FINDING CHART. — The last column of table I concerns the appearance of the objects in the sky ; for most of them, the aspect is small, starlike ; but 39 nebulae present an extended morphology.

A number of faint objects listed in the CGPN are

difficult to identify on the finding chart (FC) ; in 35 cases, the FC is incorrect or unclear in the CGPN, the objects having only been seen as a faint speck on an objective prism plate, or as a hardly visible shadow on a Palomar Sky Survey copy. In the forthcoming « Strasbourg-ESO catalogue », we will give the true position of the objects, identified on ESO sky survey plates for the southern ones. In five cases, no emission-line objects have been found ; these are probably merely plate faults.

3. Comments and conclusions.

The statistical analysis of our results shows the following distribution (Tab. II). Most of the objects considered by Sanduleak as misclassified (M) in his table I are of uncertain status, or definitely not PN ; regarding his table II of faint (F) suspected PN, we can support his conclusion that most of them are true PN. Analysing the whole sample of 264 objects, we see that 67 % of them in fact show spectral characteristics of planetary nebulae ; 32 % are PN with « normal » excitation, but showing in many cases spectral peculiarities, 4 % are PN of high excitation, and 31 % show low excitation ; it must be noted that about 20 objects of low or very low excitation show strong lines of [OIII] 436, and may perhaps represent young or proto-planetary nebulae, like IC 4997 ? (see Sanduleak and Stephenson, 1972).

The status of many objects still remains uncertain. Spectroscopic criteria are not sufficient to permit the discrimination. In the forthcoming paper II, we will try to clarify the classification, using all published observations (morphological, radio, IR, ...). In particular, good IRAS measurements (Pottasch, 1986) indicate PN colours for the 9 objects classified as « no PN ? » in our table I and noted by an asterisk ; most of these objects show a strong Balmer-decrement, due to high reddening.

Let us consider here two particularly well represented classes of objects : the « VLE » nebulae, and the symbiotic stars.

About 21 % of the objects are listed as « VLE ». The VLE class was suggested by Sanduleak and Stephenson (1972, 1973) as being a class of nebulae which have a low [OIII]/H β value and high [NII]/H α value. It is, however, not possible to distinguish the VLE objects from PN. In particular, Stenholm (1986) and Sabbadin *et al.* (1986) show that there is no obvious correlation between these two line ratios. VLE objects can be early stages of PN when the central star's temperature reaches about 2 to 3×10^4 K, giving low excitation on the nebular gases ; the objects seem generally characterized by a high density (noted « hd »).

A relatively high proportion (14 % of which 9 % are definitive) of *symbiotic stars* are identified ; many of them are not present in the catalogue of Allen (1984), and will be dealt with in a special paper by Lundström and Stenholm. It is not clear if being a symbiotic star precludes it from being a PN. In particular, the following objects show spectral characteristics on the two classes : 6 + 2°2, 7 + 1°2, 23 - 1°1, 280 - 2°1, 325 + 4°2, 346 + 8°1, 351 + 3°1, and especially 2 - 3°4 and 312 - 2°1. It is possible that in general many of the objects called PN on the basis of visual low resolution observations show, especially in the red part of their spectrum, characteristics of symbiotic stars. Thus it is very hard to specify what is the set of observed quantities which really and definitely can describe a planetary nebulae.

Acknowledgements.

We should like to express our thanks for the use of the « European Southern Observatory » facilities, at La Silla and at Garching. We are grateful to S. R. Pottasch for his very useful comments, especially concerning the classification based on IRAS data. Many thanks also to Mme Bitterly, for her help in using the HP 1000 computer of the « Institut de Physique du Globe de Strasbourg ».
